Abstract

We present PlainMamba: a simple non-hierarchical state space model (SSM) designed for general visual recognition. The recent Mamba model has shown how SSMs can be highly competitive with other architectures on sequential data and initial attempts have been made to apply it to images. In this paper, we further adapt the selective scanning process of Mamba to the visual domain, enhancing its ability to learn features from two-dimensional images by (i) a continuous 2D scanning process that improves spatial continuity by ensuring adjacency of tokens in the scanning sequence, and (ii) *direction-aware updating* which enables the model to discern the spatial relations of tokens by encoding directional information. Our architecture is designed to be easy to use and easy to scale, formed by stacking identical PlainMamba blocks, resulting in a model with constant width throughout all layers. The architecture is further simplified by removing the need for special tokens. We evaluate PlainMamba on a variety of visual recognition tasks, achieving performance gains over previous non-hierarchical models and is competitive with hierarchical alternatives. For tasks requiring high-resolution inputs, in particular, PlainMamba requires much less computing while maintaining high performance. Code and models are available at: https://github.com/ChenhongyiYang/PlainMamba.

1 Introduction

Developing high-performing visual encoders has always been one of the most important goals in computer vision [22, 23, 53, 51, 25, 26]. With high-quality visual features, a broad range of downstream tasks, such as semantic segmentation [21, 86, 95, 21, 0), object

YANG ET AL.: PLAINMAMBA

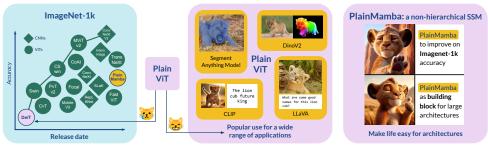

Figure 1: While hierarchical visual encoders may demonstrate superior accuracy on open-source visual recognition benchmarks, the plain non-hierarchical models have had more widespread use because of their simple structure. We investigate the potential of the plain Mamba model in visual recognition.

recognition [53, 51, 52, 56] and detection [59, 54, 59] can be tackled with relative ease. Early methods for extracting visual representations relied on hand-crafted features such as SIFT [52] and SURF [5]. A big breakthrough then came with the adoption of convolutional neural networks (CNNs) that process images with local contexts and enforce spatial equivariance [53, 54, 55]. Recently, vision transformers (ViTs) [53] obviated the need for such enforced inductive biases in favour of learnable contexts that operate on image patches [50, 52, 53]. However, despite the overwhelming success of transformers and their self-attention mechanism [0, 50, 50], the quadratic cost of attention has proved to be an obstacle to further scaling such models.

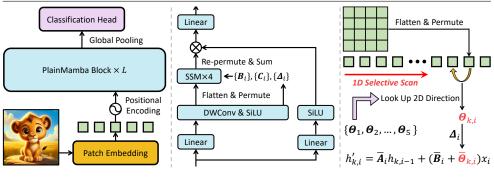

There is now understandable interest in adapting the Mamba architecture to the visual domain [49, 59, 108]. However, before we start doing that, we need to think about under what guidelines should we design our new model. As we show in Figure 1, by examining the development of recently proposed visual encoders, we find that adding more inductive biases, e.g., hierarchical structure, to the plain model such as DeiT can indeed improve a model's performance on open-source benchmarks like ImageNet. However, we should not ignore the fact that the plain ViT [23] is widely used by several popular vision foundation models [26, 46, 56, 53, 57], which suggests that simplicity in architecture design is key for multiple reasons. Firstly, maintaining a constant model width (i.e. non-hierarchical) makes it much easier to integrate features from multiple levels, as is common in dense prediction tasks such as semantic segmentation [44]. It also becomes easier to combine features across different modalities such as in CLIP $[\Box]$ or LLaVa $[\Box]$ or as parts of increasingly complex AI-powered systems. Furthermore, simpler components can be more easily optimized for hardware acceleration [III]. In addition, it has also been observed that the over-crafted models may lead to a significant gap between the performance on commonly used benchmarks and downstream tasks [5, 23]. This means benchmark performance may no longer reflect real-world usefulness, as over-engineering tends to increase model complexity and thus make it harder for others to re-use.

Motivated by the above findings, we propose **PlainMamba**: a simple Mamba architecture for visual recognition. This model integrates ideas from CNNs, Transformers and novel SSM-based models with an aim to providing easy-to-use models for the vision modality. Compared to previous visual state space models [53, [113], we simplify the architecture by maintaining constant model width across all layers of the network via stacking identical blocks as well as removing the need for CLS tokens. This allows for easy scaling and model re-use, while achieving competitive performances.

Our contributions are as follows: (1) We propose a new visual state space model we call *PlainMamba*. This architecture improves and simplifies previous attempts at extending the Mamba architecture to the visual modality. (3) We improve the SSM block by adapting selective scanning to better process 2D spatial inputs, in two ways. (i) Our **continuous 2D scanning** approach ensures that the scanning sequence is spatially continuous to improve semantic continuity. (ii) Our **direction-aware updating**, inspired by positional encoding, allows the model to encode the directionality of each scanning order to further improve spatial context. (3)We test our *PlainMamba* architecture using three different sizes (7M, 26M and 50M) and show how they perform competitively on a range of tasks, from ImageNet1K classification to semantic segmentation and object detection. Specifically, we show that PlainMamba outperforms its non-heretical counterparts, including SSMs and Transformers, while performing on par with the hierarchical competitors.

2 Related Work

Visual Feature Extractors. How to effectively extract visual features from images has been a long-standing challenge in computer vision. In the early years of deep learning, CNNs [53, 57, 56] dominated the model architecture landscape. Their induced spatial prior, through the use of convolutional filters, exploits the locality of visual features. Furthermore, stacking multiple layers increases their receptive field. Many different CNN backbone architectures have been proposed over the years [12, 14, 11], introducing new ways of exploiting spatial information [73, 96], building deeper models [83, 79], improving efficiency [53, 73, 80], adding multi-scale connections [70], scaling architectures [93], and introducing attention mechanisms [1, 9, 12, 12, 13, 14]. In recent years, ViTs have become a powerful tool for image modeling [23]. Compared to CNNs, they make fewer assumptions about data (feature locality [29], translation and scale invariance). By replacing the convolutional layers with self-attention modules, transformers can capture global relationships and have achieved state-of-the-art results on many common image benchmarks [19, 52, 10]. To adapt the original transformer architecture [12] for vision tasks, images are split into patches and converted into tokens before being fed into the transformer encoder. Within this framework, numerous works have focused on pushing the performance (e.g. LeViT, [combining transformer encoder layers and convolutions), or on reducing the costly quadratic complexity of self-attention [13, 13]. Another popular extension to ViT architectures has been the addition of hierarchical structures [27, 51, 53, 54, 52], similar to the multi-scale feature pyramids used in CNNs. The Swin Transformer [1], for instance, uses shifted windows to share feature information across scales. These multi-scale features are then used for a wide range of downstream tasks. Recent research has explored ways of using these hierarchical features within ViTs themselves [8, 22, 24, 53, 51, 51, 71, 74]. Some works [51] have examined the use of multi-resolution features as attention keys and values to learn multi-scale information. However, these extensions add complexity to the model and make it harder to

(a) Architecture of PlainMamba

(b) PlainMamba Block Architecture

(c) Direction-aware Updating

Figure 2: (a) The overall architecture of the proposed PlainMamba. PlainMamba does not have a hierarchical structure, it instead stacks L identical PlainMamba block to form the main network. For image classification, it uses global average pooling instead of the CLS to gather global information. (b) Architecture of PlainMamba block, which is similar to the Mamba []] block where the selective scanning is combined with a gated MLP. (c) The proposed *Direction-Aware Updating*, where a series of learnable parameters Θ_k are combined with the data-dependent updating parameters to explicitly inject relative 2D positional information into the selective scanning process.

effectively use its features in later stages, thus hindering widespread adoption. Indeed, recent works [50, 100] return to the original ViT architecture, as its non-hierarchical nature greatly simplifies the use of its features. In particular, the plain ViT provides greater flexibility for pre-training and fine-tuning on different tasks.

State Space Models. State Space Models (SSMs) have emerged as efficient alternatives to transformers and CNNs due to their ability to scale linearly with sequence length [52, 23]. SSMs transform the state space to effectively capture dependencies over extended sequences. To alleviate the initial computational cost of such models, S4 [53] enforced low-rank constraints on the state matrix and S5 [11] introduced parallel scanning to further improve efficiency. Furthermore, H3 [23] achieved competitive results on common benchmarks by improving the hardware utilization. Lastly, Mamba [1] parameterized the SSM matrices as functions of the input, thus allowing it to act as a learnable selection mechanism and providing greater flexibility. Follow-up works have extended selective SSMs for images [0, 52, 53, 53, 56, 12] and videos $[\mathbf{\Delta}]$ using a hierarchical structure $[\mathbf{\Sigma}]$ and bidirectional blocks $[\mathbf{\Sigma}]$, while Mamba-ND [19] introduces an architecture for multi-dimensional data. MambaIR [15] tackles image restoration, and Pan-Mamba [1] works on pan-sharpening. DiS [2] introduces SSMs to diffusion models by replacing the U-Net with an SSM backbone. While drawing inspiration from the above works, PlainMamba improves Mamba's [51] selective SSM block by adding wider depth-wise convolutions. In contrast to the Cross-Scan Module (CSM) and Mamba-ND [19], PlainMamba respects the spatio-sequential nature of image patches (see Figure 2). As opposed to [III], we do not use the CLS token.

Simplifying Visual Feature Extractors. Simplifying and unifying existing methods is equally important as improving performance. Plain architectures are robust, conceptually simpler, and scale better. ViTs [23] remove the pyramid structure of CNNs by converting images into patched tokens. This way, they easily adapt the transformer architecture for visual tasks. Another trick that stems form sequence modeling is the usage of CLS tokens for prediction, which have proven to be unnecessary for visual tasks [103]. FlexiVit [6] unified into a single architecture images with different input resolutions, and GPViT [100] improved feature resolution with a non-hierarchical transformer. Similarly, ConvNext [61] introduced a

simple CNN model that competed with state-of-the-art transformer methods. Other works, like MLP-Mixer [1] and follow-up works [1], have introduced simple architectures using only multi-layer perceptrons. The plain non-hierarchical ViT [2] has served as a simple building block for many diverse tasks. SAM [1] uses a pre-trained ViT as image encoder with minimal changes for image segmentation at large scale. DinoV2 [12, 5] uses a ViT to learn general-purpose visual features by pretraining models on curated datasets with self-supervision. Similarly, the image encoder for the CLIP [5] model consists of a basic ViT with minor modifications, allowing image-text representations to be learned with a contrastive objective. DALLE-2 [2] incorporates a ViT image encoder to extract visual features that are used for text-conditional image generation. LlaVA [5], 5] combines a vision encoder (pretrained ViT from CLIP) and an LLM for vision-language tasks.

3 Method

3.1 Preliminaries

State Space Models. SSMs are typically used to model a continuous linear time-invariant (LTI) system [\square] where an input signal $x(t) \in \mathbb{R}$ is mapped to its output signal $y(t) \in \mathbb{R}$ through a state variable $h(t) \in \mathbb{R}^m$ with the following rules:

$$h'(t) = \mathbf{A}h(t) + \mathbf{B}x(t), \quad y(t) = \mathbf{C}h'(t) + \mathbf{D}x(t)$$
(1)

where $\mathbf{A} \in \mathbb{R}^{m \times m}$, $\mathbf{B} \in \mathbb{R}^{m \times 1}$, $\mathbf{C} \in \mathbb{R}^{1 \times m}$ and $\mathbf{D} \in \mathbb{R}^{1 \times 1}$ are parameters. To make the above system usable for a discrete system, e.g., a sequence-to-sequence task, a timescale parameter $\boldsymbol{\Delta}$ is used to transform the parameters \mathbf{A} and \mathbf{B} to their discretized counterparts $\mathbf{\bar{A}}$ and $\mathbf{\bar{B}}$. In Mamba [51] and its following works [59, [113]], this is achieved with the following zero-order hold (ZOH) rule:

$$\bar{\mathbf{A}} = \exp(\Delta \mathbf{A}), \quad \bar{\mathbf{B}} = (\Delta \mathbf{A})^{-1}(\exp(\Delta \mathbf{A}) - \mathbf{I}) \cdot \Delta \mathbf{B}$$
 (2)

Afterwards, an input sequence $\{x_i\}$ (for i = 1, 2, ...) can be mapped to its output sequence $\{y_i\}$ in a similar way:

$$h'_{i} = \bar{\mathbf{A}}h_{i-1} + \bar{\mathbf{B}}x_{i}, \quad y_{i} = \mathbf{C}h'_{i} + \mathbf{D}x_{i}$$
(3)

Mamba. Since SSMs are often used to model LTI systems, their model parameters are shared by all time steps *i*. However, as found in Mamba [**S**], such time-invariant characteristics severely limit the model's representativity. To alleviate this problem, Mamba lifts the timeinvariant constraint and makes the parameters **B**, **C** and Δ dependent on the input sequence $\{x_i\}$, a process they refer to as the *selective scan*, resulting in the token-dependent $\{\mathbf{B}_i\}, \{\mathbf{C}_i\}$ and $\{\Delta_i\}$. Moreover, the SSM is combined with a gated MLP [**E**] to gain better representation ability. Specifically, the output sequence $\{y_i\}$ is computed from the $\{x_i\}$ as the following:

$$x'_{i} = \sigma(\text{DWConv}(\text{Linear}(x_{i}))), \quad z_{i} = \sigma(\text{Linear}(x_{i}))$$
(4)

$$\mathbf{B}_{i}, \mathbf{C}_{i}, \mathbf{\Delta}_{i} = \text{Linear}(x_{i}^{\prime}), \quad \bar{\mathbf{A}}_{i}, \bar{\mathbf{B}}_{i} = \text{ZOH}(\mathbf{A}, \mathbf{B}_{i}, \mathbf{\Delta}_{i})$$
(5)

$$h'_{i} = \mathbf{A}_{i}h_{i-1} + \mathbf{B}_{i}x'_{i}, \quad y'_{i} = \mathbf{C}_{i}h'_{i} + \mathbf{D}x'_{i}, \quad y_{i} = y'_{i} \odot z_{i}$$

$$\tag{6}$$

where σ denotes the SiLU activation, and \odot denotes element-wise multiply.

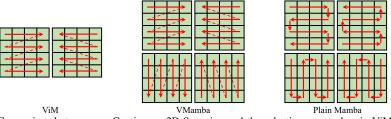

Figure 3: Comparison between our Continuous 2D Scanning and the selective scan orders in ViM [[1]] and VMamba [5]. Our method makes sure that every scanned visual token is spatially adjacent to its predecessor, avoiding potential spatial and semantic discontinuity.

3.2 Overall architecture of PlainMamba

In Figure 2, we present the model architecture of PlainMamba. Our model is divided into three main components: (1) a convolutional tokenizer that transforms an input 2D image into visual tokens, (2) the main network with a series of L identical PlainMamba blocks to learn visual representations, and (3) a task-specific head for downstream applications.

In more detail, the tokenizer will downsample the input image $I \in \mathbb{R}^{H_I \times W_I \times 3}$ into a list of visual tokens $x \in \mathbb{R}^{H \times W \times C}$, where *C* is the channel number. We set the default down-sampling factor to 16, following ViT [**C3**]. After combining the initial visual tokens with positional embeddings [**S4**] for retaining spatial information, the tokens undergo a series of transformations through the *L* PlainMamba blocks, which are designed to simplify usage by maintaining the input-output shape consistency. The final stage of the architecture involves a task-specific head, which is dependent on the particular downstream application. For instance, in image classification tasks, the image tokens are globally pooled into a vector, which is then fed into a linear classification head to produce the final output.

PlainMamba distinguishes itself from existing vision transformers [23, 53] and concurrent vision Mamba [59, 103] architectures in several key aspects. Firstly, it does not use any special tokens, such as the commonly used CLS token. Secondly, in contrast to approaches that adopt a hierarchical structure to manage feature resolution [51, 50, 59], Instead, PlainMamba maintains a constant feature resolution across all blocks. This design choice considers the recent progress made in various visual foundation models [56, 57, 57] where the plain non-hierarchical ViT is used rather than its hierarchical counterparts.

3.3 PlainMamba Block

The overall architecture comprises several identical PlainMamba blocks, forming the backbone for learning high-quality visual features. We present the structure of the PlainMamba block in Figure 2, in which we make several key adjustments to the original Mamba block to fully exploit the two-dimensional nature of image inputs. This adaptation is crucial for effectively transitioning from the inherently 1D processing paradigm of language models to the 2D domain of images. To this end, we introduce two novel techniques: (1) *Continuous 2D Scanning* and (2) *Direction-Aware Updating*. The first technique ensures that each visual token is always adjacent to the previous scanned token. By doing so, it mitigates positional bias and encourages a more uniform understanding of the image space, enhancing the model's ability to learn from visual inputs. The second technique explicitly embeds the 2D relative positional information into the selective scanning process, which allows the model to better interpret the positional context of flattened visual tokens.

Table 1: PlainMamba variants. FLOPs are measured using input size 224×224.

Model	Depth	Channels	Params	FLOPs
PlainMamba-L1	24	192	7.3M	3.0G
PlainMamba-L2	24	384	25.7M	8.1G
PlainMamba-L3	36	448	50.5M	14.4G

Continuous 2D Scanning. The selective scan mechanism is inherently designed for sequential data, such as text. Adapting this mechanism for 2D image data requires flattening the 2D viusal tokens into a 1D sequence to apply the State Space Model (SSM) updating rule. Prior research, e.g., VisionMamba [III] and VMamba [II], has demonstrated the efficacy of using multiple scanning orders to enhance model performance — such as both row-wise and column-wise scans in multiple directions. However, as shown in Figure 3 (a) and (b), in these approaches, each scanning order can only cover one type of 2D direction, e.g., left to right, causing spatial discontinuity when moving to a new row (or column). Moreover, as the parameter **A** in Equation 3 serves as a decaying term, such spatial discontinuity can also cause adjacent tokens to be decayed to different degrees, compounding the semantic discontinuity and resulting in potential performance drop.

Our *Continuous 2D Scanning* addresses this challenge by ensuring a scanned visual token is always adjacent (in the 2D space) to the previously scanned token. As shown in Figure 3 (c), in our approach, the visual tokens are also scanned in four distinct orders. When reaching the end of a row (or column), the next scanned token will be its adjacent, *not the opposite*, token in the next column (or row). Then, the scanning continues with a reversed direction until it reaches the final visual token of the image. As a consequence, our method preserves spatial and semantic continuity and avoids potential information loss when scanning non-adjacent tokens. Furthermore, in practice the model usually takes input images of the same size, meaning our method can be easily implemented and efficiently run by pre-computing the permutation indexes.

Direction-Aware Updating. As shown in Equation 3, the contribution of a token x_i to the hidden state h_i in the selective scan is determined by the parameter \mathbf{B}_i , derived from x_i itself. In language models, the sequential order naturally dictates the positional relationship between tokens, allowing the model to "*remember*" their relative positions. However, in our Continuous 2D Scanning, the current token can be in one of four possible directions relative to its predecessor. This challenges the model's ability to discern the precise spatial relationship between consecutive tokens based on \mathbf{B}_i alone. Our *Direction-Aware Updating* is therefore proposed to address this challenge. Drawing inspiration from the relative positional encoding mechanisms in vision transformers [23], we employ a set of learnable parameters $\{\mathbf{\Theta}_k \in \mathbb{R}^{m \times 1}\}$ (for k = 1, 2, ..., 5), representing the four cardinal directions plus a special BEGIN direction for the initial token. These parameters are summed with the data-dependent \mathbf{B}_i to enrich the selective scan process with directional information. Specifically, with x_i and z_i following Equation 3, our *Direction-Aware Updating* is formulated as follows:

$$h'_{k,i} = \bar{\mathbf{A}}_i h_{k,i-1} + (\bar{\mathbf{B}}_i + \bar{\mathbf{\Theta}}_{k,i}) x_i$$
(7)

$$y'_{i} = \sum_{k=1}^{4} (\mathbf{C}_{i} h'_{k,i} + \mathbf{D} x_{i}), \quad y_{i} = y'_{i} \odot z_{i}$$
(8)

where *k* spans the four distinct scanning directions introduced by our *Continuous 2D Scanning*. Alternatively, for the initial token of each scan, we instead add the final $\bar{\Theta}_{k=5}$ vector. The term $\bar{\Theta}_{k,i}$ represents the discretized $\Theta_{k,i}$ using Δ_i .

3.4 Model Variants of PlainMamba

As shown in Table 1, we present three different model variants of PlainMamba. Specifically, from PlainMamba-L1 to PlainMamba-L2, we scale the model width, i.e., feature channel numbers, and keep the model depth to 24. From PlainMamba-L2 to PlainMamba-L3, we scale both model width and depth. The FLOPs are measured using 224×224 inputs, and we follow the official Mamba codebase to compute the FLOPs of the selective scan process.

4 **Experiments**

In the main paper, we quantitatively compare PlainMamba with previously proposed models on four visual recognition tasks: image classification, object detection, instance segmentation, and semantic segmentation. Please refer to our supplementary materials for further ablation studies.

4.1 Experiment Settings

ImageNet Classification. We build our codebase following [100], which is a commonly used training recipe. Specifically, for the ImageNet-1k experiments, we train all PlainMamba models for 300 epochs using AdamW op-Following $[\Box]$, we set the timizer. batch size to 2048, weight decay to 0.05, and the peak learning rate to Cosine learning rate schedul-0.002. ing is used. For data augmentation, we used the commonly used <mark>82</mark>], recipe [21, 22, which in-60. cludes Mixup [111], Cutmix [112], Random erasing [106] and Rand augment [14].

ADE20K Semantic Segmentation. We follow common practice [22, 51, 100] to use Uper-Net [23] as the segmentation network. Unlike XCiT [0], we do not explicitly resize the constant resolution feature maps into multi-scale. Following [50], we train all models for 160 iterations with batch size 16 and set the default training image size to 512×512 .

COCO Object Detection and Instance Segmentation. Following [\square], we test Plain-Mamba's ability on COCO object detection and instance segmentation using both the two-stage Mask R-CNN [\square] and the single-stage RetinaNet [\square]. For both models, we report the results of both 1× schedule. Following [\square], we use ViTAdapter [\square] to compute multi-scale features to fit the FPN network structure. We use the commonly used training settings proposed in [\square] to keep a fair comparison.

4.2 Main Results

ImageNet-1K Classification. In Table 2, we report the ImageNet-1K experiment results. We compare PlainMamba with three different kinds of visual feature extractors: CNNs, vision transformers, and SSMs. In addition, the comparison includes both hierarchical and nonhierarchical models. Firstly, when comparing with SSMs, our model is doing better than the recently proposed Vision Mamba [III] and Mamba-ND [II]. For example, PlainMamba-L2 achieves a 2.4% higher accuracy than Mamba-ND-T while they share a similar model size. These results validate PlainMamba's effectiveness as a non-hierarchical SSM. Secondly, when compared with CNNs and transformers, our model achieves better performance than the non-hierarchical counterparts. For example, PlainMamba-L2 achieves 1.7% better accuracy with DeiT-Small. Moreover, PlainMamba also achieves similar performance when compared with hierarchical models. For example, when the model size is around 25M, our model achieves 0.3% better accuracy than Swin-Tiny, validating PlainMamba's ability as a general feature extractor. On the other hand, the hierarchical VMamba [53], together with other hierarchical transformers, do achieve a better accuracy than ours. As we explained in Section 1, hierarchical models tend to perform better than non-hierarchical ones in visual recognition. As the main motivation of our work is to develop a simple Mamba architecture, a bit inferior ImageNet accuracy is acceptable.

ADE20K Semantic Segmentation We report our model's ADE20K semantic segmentation performance in Table 3. Similar to the ImageNet-1k and COCO experiments, here the competing models include both hierarchical and non-hierarchical backbones in three types of visual feature extractors. The results again suggest that PlainMamba achieves the best performance among the non-hierarchical models. For example, with similar parameter amounts, PlainMamba-L2 outperforms the high-resolution (patch size of 8) XCiT-S12/8 model [I] with a much lower computation cost. Moreover, PlainMamba-L2 also outperforms the hierarchical Swin-Transformer-Tiny [1], achieving better mIoU while having a lower model size and FLOPs. At the same time, PlainMamba is also doing better than the concurrent Vision Mamba [

Table 3: ADE20K semantic segmentation using UperNet. The FLOPs are computed using input size 512×2048.

PlainMamba-L1	X	35M	174G	44.1
PlainMamba-L2	x	55M	285G	46.8
PlainMamba-L3	×	81M	419G	49.1

For instance, PlainMamba-L2 achieves a 1.9 higher mIoU than ViM-S. This result verifies our model's effectiveness in extracting fine-grained visual features, which is essential for the pixel-wise semantic segmentation task.

COCO Object Detection and Instance Segmentation. We report the results of Mask R-CNN object detection and instance segmentation in Table 4. With similar FLOPs and many fewer parameters, PlainMamba-L1 achieves 44.1 AP^{bb} and 39.1 AP^{mk} when using 1× training schedule, while Swin-Small achieves 44.8 AP^{bb} and 40.9 AP^{mk} . We also observe that

Table 4: Mask R-CNN object detection and instance segmentation on MS COCO *mini-val* using $1 \times$ schedule. We use ViTAdapter [III] to compute multi-scale features. FLOPs are computed using input size 1280×800 .

hierarchical models tend to work better than non-hierarchical models. Although our model achieves lower performance than some hierarchical models, e.g., the concurrent VMamba [Σ], PlainMamba achieves the best performance among its non-hierarchical counterparts. For instance, when using 1× training schedule, PlainMamba achieves 3.1 higher AP^{bb} and 1.6 higher AP^{mk} than DeiT-T when they are both equipped with the ViTAdapter [\Box]. These results demonstrate that PlainMamba is able to extract good local features, which is important to the object-level tasks like instance segmentation. On the other hand, we also admit that PlainMamba is performing worse than the hierarchical VMamba [Σ]. We attribute such inferiority to the multi-resolution architecture of FPN-based [Σ] Mask R-CNN, which is more naturally suitable to the hierarchical designs.

5 Conclusion

We present PlainMamba, a plain SSM-based model for visual recognition. Our model is conceptually simple because it uses no special tokens or hierarchical structure, making it a perfect counterpart to the widely used plain vision transformer. The results show that PlainMamba achieves superior performance to previous non-hierarchical models, including the concurrent SSM-based models, and can perform on par with the high-performing hierarchical models. We hope our model can serve as a baseline for future research in this area.
